Abstract: There is no strong evidence indicating the optimal treatment for breast cancer (BC) and no specific prognostic model. The aim of this study was to establish nomograms to predict the overall survival (OS) of BC patients receiving chemoradiotherapy and surgery, thereby quantifying survival benefits and improving patient management. A total of 1877 patients with primary nonmetastatic BC who received chemoradiotherapy and surgery from 2010 to 2019 were identified from the Surveillance, Epidemiology and End Results (SEER) database as the training cohort, 804 as the internal validation cohort, and 796 patients from the First Affiliated Hospital of Zhengzhou University (n=324) and Jiaxing Maternal and Child Health Hospital (n=472) as the external validation cohort. Least absolute shrinkage and selection operator (LASSO), univariate, and multivariate Cox regression analyses were performed in the training cohort to determine independent prognostic factors for BC, and a nomogram was constructed to predict 3-year, 5-year, and 8-year OS. The final model incorporated 7 factors that significantly affect OS: race, location, positive regional nodes, T stage, N stage, subtype, and grade. The calibration curves showed good consistency between the predicted survival and actual outcomes. Time-dependent receiver operating characteristic (ROC) curves and the time-dependent area under the curve (AUC) confirmed that the accuracy and clinical usefulness of the constructed nomograms were favorable. Decision curve analysis (DCA) and net reclassification improvement (NRI) also demonstrated that this nomogram was more suitable for clinical use than the 7th American Joint Committee on Cancer (AJCC) tumor node metastasis (TNM) staging system and the previous prediction model. In the training cohort and the internal validation cohort, the concordance indices (C-index) of the nomogram for predicting OS (0.723 and 0.649, respectively) were greater than those of the 7th AJCC TNM staging system and the previous prediction model. In addition, based on Kaplan-Meier (K-M) survival curves, the survival differences among different risk stratifications were statistically significant, indicating that our risk model was accurate. In this study, we determined independent prognostic factors for OS in patients with primary nonmetastatic BC treated with chemoradiotherapy and surgery. A new and accurate nomogram for predicting 3-, 5-, and 8-year OS in this patient population was developed and validated for potential clinical applicability.

Keywords: Breast cancer, chemoradiotherapy, nomogram, SEER program, risk classification system, overall survival

Introduction

Breast cancer (BC) is one of the most common malignancies in women, accounting for approximately 30% of new cancers occurring in women [1-3], and its mortality rate (15%) is the second highest among all malignancies in women [4]. It has been reported that since the middle of the last century, the incidence of BC has increased at a rate of 0.5% per year worldwide. In 2020, there were more than 2.3 million new cases of BC and 685,000 BC-related deaths worldwide, and the number of new cases is expected to increase to more than 3 million by 2040, with the number of deaths reaching 1 million annually. In the United States, the 5-year survival rates for localized, regional, and distant metastatic BC are 99%, 85%, and 27%, respectively [5].

The management of BC is multidisciplinary [5]. Factors affecting the prognosis of BC patients include age, race, ethnicity, body weight, tumor and disease characteristics, response to treatment, etc. [5], and BC can also be classified into different subtypes according to hormone receptor positivity, human epidermal growth factor receptor type 2 (HER2) status, and tumor cell proliferation activity. TNM staging is performed according to tumor size, local aggressiveness, and lymph node and distant metastasis status [6]. Neoadjuvant and adjuvant therapies are recommended for each subtype and stage. For the vast majority of stage I-III patients with operable early BC, the main treatment mode is surgery, and the standard of combined adjuvant therapy is surgery + continuous chemotherapy (CT) + radiotherapy (RT) [7-9], but their optimal integration is still controversial [7, 9, 10]. At present, the efficacy of treatment for stage IV BC patients is still poor, but surgery, chemotherapy, radiotherapy, immunotherapy and targeted therapy have been widely used. Among them, the role of RT, commonly used in palliative care for BC patients, was highlighted by the National Cancer Database study. With the development of imaging methods, RT can be used as a definitive treatment for some stage 0-III patients who explicitly refuse surgery, providing more accurate nonsurgical treatment than previously possible [11, 12]. Preclinical studies have shown that RT has an antitumor effect by initiating and activating cytotoxic T cells, activating dendritic cells and type I interferon-dependent immune responses, and upregulating PD-L1 on bone marinederived suppressor cells [13-17]. Therefore, choosing the best treatment for each patient, accounting for their wishes, may become more important in the future.

Interestingly, with early screening and improved treatment for BC, BC mortality has decreased by 42% over the past 30 years [5]. Therefore, the early identification of BC patients and accurate risk stratification of BC are of great importance in clinical practice and can help doctors adopt more active individualized treatments, especially for high-risk patients. Currently, there are many prognostic models based on traditional survival analysis methods, such as TNM staging, but they often ignore conflicting events. In addition, while independent prognostic factors associated with OS have been identified in BC, there is currently no universally accepted scoring system to predict long-term OS in this population. Nomograms are a simple and multivariable visualization tool for quantifying and predicting risk and prognosis in the field of oncology [18-22], and these models are based on key variables such as traditional clinicopathological features to more accurately estimate individual survival to aid clinical decision-making and promote the development of precision medicine. Nomograms for predicting the prognosis of BC patients have been developed and verified [23, 24].

For these reasons, we used the SEER database, which contains much multicenter and high-quality study data, and retrospective data from two Chinese hospitals to identify independent prognostic factors associated with OS in this subpopulation and developed a new nomogram for 3-, 5-, and 8-year OS prediction. The nomogram was compared with the traditional 7th AJCC TNM stage and the previous prediction model to provide some reference for identifying high-risk patients and making individualized treatment decisions in clinical practice.

Material and methods

Data source and patient selection

First, we extracted and screened the clinical data of BC patients from the SEER public database from 2010 to 2019, gradually identified patients who met the inclusion criteria, and finally included 2681 BC patients in the study, including 1877 patients as the training cohort and 804 patients as the internal validation cohort. In addition, a total of 796 BC patients treated at the First Affiliated Hospital of Zhengzhou University and Jiaxing Maternal and Child Health Hospital from January 2009 to August 2022 were retrospectively analyzed for external verification.

In both the training cohort and the validation cohort, the inclusion criteria were as follows: (1)

Figure 1. Flow chart of the design. SEER, Surveillance, Epidemiology and End Results; AJCC, American Joint Committee on Cancer; LASSO, least absolute shrinkage and selection operator; DCA, decision curve analysis; ROC, receiver operating characteristic; AUC, area under the curve; C-index, concordance index; NRI, net reclassification improvement; TNM, tumor node metastasis.

patients with BC confirmed by histopathological examination according to the malignant behavior coded by ICD-O-3/WHO 2008; (2) patients with BC as the first tumor without multiple primary malignancies and without metastases of other sites; (3) patients with TNM stage I-III who received chemoradiotherapy and surgery; (4) patients with complete follow-up data on OS and a survival time over 1 month; and (5) patients with complete case information. The detailed flow chart of the study population selection process is shown in **Figure 1**. The study was carried out in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Jiaxing Maternal and Child Health Hospital.

Endpoints and study variables

The following variables were selected as potential prognostic factors at the time of diagnosis: age, sex, race, marital status, laterality, location, regional nodes examined, positive regional nodes, histologic type, T stage, N stage, TNM stage, grade, subtype, and tumor size.

We used the 7th TNM staging system to define T, N, M, and TNM staging in patients with clinical stages. Tumor locations were divided into the upper-outer quadrant, up-per-inner quadrant, lower-outer quadrant, lower-inner quadrant and others. Histologic type was classified into infiltrating ductal carcinoma (IDC) and others. The histologic types were divided into well differentiated (Grade I), moderately differentiated (Grade II), poorly differentiated (Grade III) and undifferentiated (Grade IV). Subtypes were divided into HR-/HER2-(triple-negative), HR-/HER2+ (Her2-enriched), HR+/HER2- (luminal A)

and HR+/HER2+ (luminal B). Tumor size was assessed according to maximum tumor diameter and was classified as less than 2 cm or greater than 2 cm. The outcome of the study was OS, defined as the time between the date of diagnosis and the date of death from any cause or the last follow-up. In the training cohort, the median OS time was 73.0 months (range 5.0~119.0 months); the median OS time in the internal validation cohort was 74.0 months (range 6.0~119.0 months); and the median OS time in the external validation cohort was 86.2 months (range 9.7~398.8 months). All patients in the validation cohort were followed up by telephone or in-hospital visits. For the validation cohort, the follow-up period ended on February 17, 2023.

Statistical analysis

The clinical characteristics and prognostic data of patients in the training cohort were extracted from large-scale SEER cancer registry data by SEER*Stat software (version 8.3.5). SPSS 26.0 software and RStudio 4.2.2 were used for statistical analyses and to graph the data. To compare variables between the training and validation cohorts and compare categorical variables, Pearson Chi-square tests were used. P<0.05 was considered statistically significant, and all tests were two-sided.

The training cohort was used to develop the nomogram, while the validation cohort was used to verify the model efficacy. LASSO, univariate, and multivariate Cox regression analyses were performed in the training cohort to identify independent prognostic factors associated with OS in BC patients, and hazard ratios (HRs) and 95% confidence intervals (CIs) were calculated. The variables selected by LASSO and those with P<0.10 in univariate Cox analysis were included in the multivariate analysis for mixed, forward, backward and stepwise regression analyses. The variable combination with the smallest Akaike information criterion (AIC) value was selected by analysis of variance (ANOVA), and the variables with P<0.05 were eligible to be used to generate the nomograms. Each variable was converted to a corresponding 0-100 scale, and then the points assigned for each variable were summed to obtain the total score, which was finally converted to predict the OS of BC patients at 3, 5, and 8 years. Finally, according to the median risk score of the model, patients in the training cohort and the validation cohort were assigned to a highrisk group or a low-risk group. K-M curves and log-rank tests were used for survival analyses to explore the differences in survival rates

among BC patients with different risk classifications. Time-dependent ROC curves, timedependent AUCs and calibration curves (1000 samples, 45-degree line as the best model) were used to evaluate the prediction accuracy and discrimination of the nomogram. DCA was used to test the clinical benefit and application value of the nomogram. We also calculated the C-index and NRI and compared the nomogram with the 7th AJCC TNM staging system and 5 previous prediction models to further demonstrate the superiority of our model in terms of clinical benefit and practicability. If the C-index and AUC values were between 0.5 and 0.6, between 0.6 and 0.7, or greater than 0.8, the model's predictive performance was considered poor, average, or good, respectively. An NRI >0 indicated a positive improvement, meaning that the prediction ability of the new model was improved compared with that of the old model. An NRI <0 indicated a negative change, indicating a decline in the predictive power of the new model.

Results

Patient characteristics

Table 1 shows the demographic and clinicopathological characteristics of the training cohort (n=1877), internal validation cohort (n=804) and external validation cohort (n=796). Interestingly, except for regional node positivity, there was no significant difference between patients in the training cohort and the internal validation cohort, indicating a uniform distribution between them ($P \ge 0.05$). Moreover, there were no significant differences in the distribution of sex or laterality between the training cohort and the external validation cohort. Although the remaining variables were different between these two cohorts (P<0.05), overall, half of the patients had tumors in the upper quadrant, and more than 60% of the patients were married, had more than 3 regional nodes examined, had a tumor size greater than 2 cm and had a positive ER status. The histologic type of BC in more than 80% of patients was IDC, more than 80% of patients had stage T1+T2 or N0+N1 disease, and the grade was concentrated in stages II and III. However, it is worth noting that positive regional lymph nodes were detected in 88.1% of patients in the external validation cohort and less than 54.6% in

Figure 2. Selection of the prognostic factors using LASSO Cox regression. A. For clinicopathological features, LASSO coefficient profiles are plotted vs. log λ sequences. The dotted vertical line shows the nonzero coefficients, where 7 nonzero coefficients are included. B. Tuning parameter λ based on minimum criteria in the LASSO regression. The partial likelihood binomial deviance is plotted against log λ . By using the minimum standard error of the minimum criteria, dotted vertical lines are set at the optimal values log λ , where factors are selected. LASSO, least absolute shrinkage and selection operator.

the SEER cohort. Other significant differences were race, where the SEER cohort was overwhelmingly white, and all patients in the external validation cohort were Asian (100%). In addition, 52.6% of patients in the SEER cohort had luminal A cancer, while the main subtypes in the external validation cohort were triplenegative and luminal B.

Screening for predictive factors

Based on the included variables, LASSO analysis was first used (**Figure 2**) to identify 14 indicators related to OS, which were input into the univariate Cox regression model. In addition, multivariate Cox regression analysis was performed using variables with P<0.10 in univariate Cox regression analysis, and the influence of confounding variables was eliminated to further determine independent prognostic factors

for BC patients (**Table 2**). The independent risk factors included grade (P=0.005), race (P=0.004), positive regional nodes (P=0.003), location (P=0.024), AJCC-T stage (P<0.001), AJCC-N stage (P=0.015), and subtype (P<0.001). In addition, K-M curves showed that the above indices were significantly correlated with OS (P<0.05) (**Figure 3**). The independent predictors above, including location, achieved AUC ranges of greater than 0.5 for predicting 10-year OS indicating reasonable estimates (**Figure 4**).

Development and Validation of the nomograms

Here, we set up two nomograms. Figure 5A was generated according to the 7th AJCC TNM staging system and contains the T, N, and M stages. Figure 5B shows a complex model containing 7

Table 2. Univariate and multivariate Cox analyses on variables for the prediction of OS of BC patients

Abbreviations: BC, breast cancer; OS, overall survival; AJCC, American Joint Committee on Cancer; TNM, tumor node metastasis.

statistically significant variables based on multivariate analysis of the training cohort. Both nomograms were used to predict OS probabilities at 3, 5, and 8 years. Simply put, each factor and subtype were assigned a score on the scoring table, and by adding the scores together and locating the corresponding position on the bottom scale, we calculated the probability of 3-, 5-, and 8-year OS. Next, the nomogram was verified for predictive accuracy in the training and verification cohorts. We tested 1000 bootstrap samples for the training cohort, internal validation cohort and external validation cohort, and the calibration graphs showed that the nomogram performed well in these cohorts (Figure 6).

Comparison of different models

To further compare the clinical application prospects and predictive performance of the nomogram with that of the 7th AJCC TNM staging system, we plotted DCA curves (**Figure 7**) and ROC curves (**Figure 8**). In the training cohort, the DCA curve showed that our model had a significantly better performance. In addition, in these cohorts, our model showed higher AUCs for all ROC curves, indicating superior prognostic accuracy over the 7th AJCC TNM staging system. In the training cohort, internal validation cohort and external validation cohort, the AUCs of the nomogram in predicting 3-, 5-

and 8-year OS were 0.732, 0.761, and 0.715; 0.683, 0.644, and 0.676; and 0.869, 0.845, and 0.742 respectively. Similarly, these values were 0.640, 0.675, and 0.651; 0.625, 0.617, and 0.657; and 0.947, 0.890, and 0.807, respectively, for the 7th AJCC TNM staging system (**Figure 8**).

Based on the training cohort, the C-index of the nomogram was 0.723, the 95% CI was 0.694~0.752, the C-index of the 7th AJCC TNM staging system was 0.652, and the 95% CI was 0.623~0.681. In the internal validation cohort and external validation cohort, the C-indices of the above 2 models were 0.649 and 0.623 and 0.757 and 0.806, respectively (Table 3). In addition, whether in the training cohort, internal validation cohort or external validation cohort, compared with the nomogram in this paper, the NRI of the 7th AJCC TNM staging system and the previous prediction model were all less than or equal to 0 (Table 4). Overall, compared with the 7th AJCC TNM staging system and the previous prediction model, the new model we constructed had a better overall prediction performance (Figure 9).

Nomogram performance in risk group stratification

To facilitate personalized management, it is necessary to classify patients according to

Breast cancer patients underwent chemoradiotherapy and surgery

Figure 3. K-M curves for risk stratification (A) in the whole cohort and (B) in the training cohort. K-M, Kaplan-Meier.

Figure 4. The time-dependent AUC curves of grade, location, T stage, race, regional nodes positive, subtype, N stage, and TNM stage for OS (A) in the whole cohort, (B) in the internal validation cohort, and (C) in the external validation cohort. AUC, area under the curve; OS, overall survival.

Figure 5. Two nomograms used to predict 3-, 5- and 8-year OS rates of BC. A. Model 1 nomogram was established according to tumor AJCC-TNM stage. B. Model 2 nomogram was established according to race, location, regional nodes positive, subtype, T stage, N stage, and grade. For each variable, the value of an individual is placed on the axis, and a line is drawn upward to determine how many points exist for each variable. The survival axis is drawn below the total points axis, which is then used to determine the 3-, 5-, and 8-year OS rates. AJCC, American Joint Committee on Cancer; BC, breast cancer; OS, overall survival.

their mortality risk. Each patient in the cohort was given a risk score based on the nomogram model, and the median risk score was set as the threshold value. We then evaluated the performance of our risk model by plotting the K-M survival curves of OS for the training and validation cohorts (**Figure 10**). The significant difference in survival seen between the high-risk and low-risk groups indicated that our risk model was accurate (*P*<0.001).

Discussion

We developed and constructed a nomogram with clinical value based on data from the SEER database and included all available factors affecting the prognosis of BC. Finally, race, location, regional node positivity, subtype, AJCC-T stage, AJCC-N stage, and grade were identified as independent prognostic factors for OS. Notably, we used data from the Chinese population for external validation, and the calibration curve, C-index, time-dependent ROC curve, time-dependent AUC, DCA, IDI, NRI and other aspects showed

Figure 6. Assessment of nomogram used to predict 3-, 5-, and 8-year OS rates in the patients with BC in the (A) training cohort, (B) internal validation cohort, and (C) external validation cohort. The X-axis represents the model-predicted survival, and the Y-axis represents actual survival. The bar represents 95% CI as measured by K-M analysis, and the dotted line represents the ideal reference line. BC, breast cancer; OS, overall survival; K-M, Kaplan-Meier; CI, confidence interval.

that our model performed well in the validation cohort. It was proven that our nomogram has better prediction and discrimination ability than the 7th AJCC TNM staging system and the previous prediction model. The BC patients were categorized in high- and low-risk subgroups to provide comprehensive guidance for clinical practice.

The AJCC-TNM staging system is the most classic risk stratification and treatment strategy selection system for cancer patients [25, 26] and is commonly used to evaluate the prognosis of BC patients and determine treatment strategies [27, 28]. Our study showed that the HRs for T stage, N stage and TNM stage, and AJCC 7th edition in multivariate analysis were 1.644 (1.371~1.971) (*P*<0.001), 1.282 (1.048~ 1.567) (*P*=0.015), and 1.091 (0.780~1.527) (*P*=0.609), respectively. The T, N, and M stages

of tumors can affect the prognosis of BC. With progression in TNM stage, the prognosis of patients deteriorates significantly, and higher stages are negatively correlated with the survival time of patients [29]. However, this most widely used system ignores many factors that have been shown to be highly correlated with OS and does not accurately identify survival differences between cancer subtypes, which was one of the motivations for this study.

In terms of social demographic data, marital status, age and race were found to be independent risk factors for BC patients. Studies have shown that marriage can reduce the risk of death by 25%. Unmarried patients often lack care and support from spouses, leading to increased psychological stress, and are more likely to suffer from chronic psychological distress, bad living habits, endocrine system dis-

Figure 7. The DCA curves were plotted based on 3-, 5-, and 8-year OS benefits in the (A) training cohort, (B) internal validation cohort, and (C) external validation cohort. DCA, decision curve analysis; OS, overall survival.

orders and declines in immune system function [30, 31], ultimately accelerating tumor growth and patient death [32]. Age is generally regarded as an important reference factor affecting the occurrence and development of tumors, their biological characteristics and the prognosis of BC. Studies have found that the incidence of BC increases with age, doubling roughly every 10 years until the increase in BC begins to slow during menopause [33]. In terms of prognosis, it is generally accepted that older patients have higher mortality, which may be related to the fact that they tend to have more underlying conditions, such as hypertension, hyperlipidemia, heart disease, cerebrovascular disease, and diabetes [34], which can lead to poor tolerance and compliance with treatment. However, in terms of molecular pathology, young BC patients (<35 years of age) were

found to have worse pathology and classification (with larger tumors, positive lymph nodes, higher histological grade, nonluminal disease, and higher Ki-67 expression), worse prognosis, and higher rates of metastasis and recurrence [35]. In addition, our study suggested that black women have a worse prognosis than white women, which may be related to black patients often having poorer economic conditions and living environments and less access to medical resources and surgical treatment [1, 36-40].

BC patients were grouped as having luminal A, luminal B, HER2-enriched and triple-negative subtypes of cancer based on three key therapeutic targets, ER, PR and HER2. Consistent with epidemiological studies, our study found significant differences in the prognoses of BC

patients with different molecular subtypes, among which the triple-negative molecular subtype had a poor prognosis. There is evidence for an interaction between the ER and HER2 pathways. The ER pathway can be used as a bypass activation mechanism of downstream signals and may activate the HER2 pathway [41]. The activated HER2 signaling pathway will further promote the activity of the ER pathway, ultimately leading to impaired endocrine therapy responses and possibly altering the tumor response to HER2-targeted therapy [42]. In addition, some neoadjuvant clinical studies targeting anti-HER2 have shown a lower pathologic complete response rate (pCR) in patients with the luminal B subtype than in patients with the luminal A subtype [43].

This study included high-quality SEER data in the training cohort and a multicenter Chinese population as the validation cohort to ensure accuracy in identifying independent risk factors affecting OS in BC patients. To our knowledge, this study established a competitive risk model for predicting OS in BC patients and verified the accuracy of the model. However, there are still potential limitations to the study. First, this study is a retrospective study, and selection bias may lead to bias in the results. Second, the SEER database lacks specific information about systemic therapy and some important molecular factors, such as HER2-targeted therapy, endocrine therapy, immunotherapy and treatment response; programmed death ligand 1 (PD-L1) expression or microsatellite status; tumor markers, family history, menstrual history, fertility status, and weight. If more comprehensive patient information can be included, the prediction accuracy of the model can be improved; however, with further improvement of the database, these problems can be further solved. Finally, large prospective studies or high-quality randomized controlled trials are needed for further validation.

Conclusions

In conclusion, we developed and validated a competitive nomogram and risk classification system to reliably predict OS at 3, 5, and 8 years in BC patients, with superior prognostic value compared to the 7th AJCC TNM staging system alone and compared to a previously published prediction model. This nomogram can improve prognosis assessment, better predict individual survival, guide follow-up management strategies, and assist in facilitating individualized therapy. The created nomogram has promising clinical application prospects.
